An interface modification of (LaCa)MnO$_2$-BaTiO$_3$ superlattices was found to massively influence magnetic and magnetotransport properties. Moreover it determines the crystal structure of the manganite layers, changing it from orthorhombic ($Pnma$) for the conventional superlattice (cSL), to rhombohedral ($R3c$) for the modified one (mSL). While the cSL shows extremely nonlinear ac transport, the mSL is an electrically homogeneous material. The observations go beyond an oversimplified picture of dead interface layers and evidence the importance of electronic correlations at perovskite interfaces.

DOI: 10.1103/PhysRevB.82.113101

Interfaces of complex oxides have gained much attention since the discovery of a high-mobility quasi-two-dimensional electron gas at the TiO$_2$/La$_2$O$_3$ interface between insulating LaAlO$_3$ (LAO) and SrTiO$_3$ (STO). This unexpected finding disclosed a new role of interfaces in oxide heterostructures. Thereby the reconstruction of the interface is discussed to avoid an electrostatic potential, otherwise building up in the lanthanum perovskite. For this reconstruction either electrons redistribute or ions rearrange through relaxation or deviation from stoichiometry. The charge transfer can effectively dope the materials in a rather thin region in the vicinity of the interface and the resulting change in carrier concentration due to the presence of an interface can be termed “interface doping.” For strongly correlated electron systems it is well known that the carrier concentration massively influences the properties of the material. A prominent example is the class of perovskite manganites, which are interesting not only because of high spin polarization in the ferromagnetic phase, but also due to the fascinating JT polarons into pairs of correlated polarons or bipolarons is now argued to bring about the strong localization at these JT polarons. Localization is stabilized by the Jahn-Teller effect, from the tetrahedral $\text{Mn}^{3+}$ ions, giving rise to JT polarons, that are discussed to be the main type of charge carrier at all temperatures. Even for optimal-doping ($0.2 \leq x \leq 0.4$) correlated JT polarons have been observed by neutron and x-ray scattering with the wave vector of these short-range JT-distorted regions being $q = \left[\frac{1}{2}, \frac{1}{2}, 0\right]$. The loss of FM order in La$_2$/Ca$_{1/3}$/MnO$_3$ (LCMO) and La$_{2-2y}$/Sr$_{1/3}$/MnO$_3$ (LSMO) below a critical film thickness and the poor performance of LSMO-STO-LSMO tunnel junctions at elevated temperatures have been connected to the worsening of double exchange at manganese interfaces. The breakup of the Mn-O chains has been accounted for the conventional superlattice that cSL, to rhombohedral ($R3c$) for the modified one (mSL). While the cSL shows extremely nonlinear ac transport, the mSL is an electrically homogeneous material. The observations go beyond an oversimplified picture of dead interface layers and evidence the importance of electronic correlations at perovskite interfaces.

in a good agreement with the nominal thicknesses. Rocking curves obtained by XRD show very broad distributions for both SLs (FWHM$_{cSL}$ = 1.18° ± 0.01° and FWHM$_{mSL}$ = 1.38° ± 0.01°) which we attribute partly to the low quality of MgO substrates. A detailed study of the crystal and chemical structure of SLs was performed on cross section and plan-view specimens by means of TEM. Plan-view and cross-section electron-diffraction (ED) [Figs. 2(a) and 2(b)] patterns clearly show heteroepitaxial growth of all layers for both SLs. Cross-section high-resolution TEM (HRTEM) images confirm epitaxial growth of SLs and show coherent, atomically flat, and sharp interfaces [Figs. 1(c) and 1(d)]. The extra LMO layers in mSL are not visible in HRTEM image but, obviously, introduce significant structural differences between cSL and mSL as it can be detected by ED and HRTEM. The LCMO layer of the mSL exhibits the unusual $R\bar{3}c$ structure in contrast to most bulk samples$^{24}$ and cSL LCMO showing both Pnma structure. The lattice parameters of the manganite layers in pseudocubic notation are $a_{cSL}$ = 3.87±0.02 Å and $c_{cSL}$ = 3.82±0.02 Å for the conventional superlattice and $a_{mSL}$ = 3.88±0.01 Å and $c_{mSL}$ = 3.87±0.01 Å for the modified superlattice. The structure of BTO of both SLs is found to be close to $P4mm$. The tetragonality of the BTO layers is $c/a = 1.04 ± 0.005$ for the conventional and $c/a = 1.025 ± 0.005$ for the modified SL. Energy-filtered TEM of mSL (Fig. 3) shows well-defined chemical separation of LCMO and BTO layers. Intermixing of LCMO and LMO on the small scale of several monolayers nonetheless can not be excluded. In order to analyze strain fields, the geometrical phase analysis (GPA) method$^{25}$ has been applied to HRTEM images of cSL and mSL. The results of GPA along the growth direction are shown in Figs. 2(e) and 2(f) and reveal inhomogeneously strained cSL, in contrast to the mSL heterostructure which looks homogeneously strained.

Magnetic properties of the SLs have been measured with external field applied parallel to the film plane. The temperature dependence of the magnetization of both SLs, see Fig. 4(a) shows a rather broad ferromagnetic transition, typical for thin LCMO layers$^{26,27}$ The magnetic Curie temperatures of the SLs are $T_{c}^{cSL}$ = 245 K and $T_{c}^{mSL}$ = 253 K. Magnetic hysteresis $M(H)$, shown in Fig. 4(b) was measured at $T$=10 K after cooling without [zero-field cooling (ZFC)] and with an external field $\mu_0 H$=5 T applied during cooling (FC). The saturation magnetization ($M_s$) of the SLs after FC is as large as $M_s^{cSL} = 287$ emu cm$^{-3}$ and $M_s^{mSL} = 393$ emu cm$^{-3}$ which is smaller than the bulk value, $M_s^{bulk} = 650$ emu cm$^{-3}$. In the case of the mSL, additional LMO layers are expected to contribute to the magnetic moment and therefore the volumes of both LCMO and LMO were considered calculating $M_s^{mSL}$. The corresponding coercivities are $H_c^{cSL} = 721$ Oe and $H_c^{mSL} = 536$ Oe. Interestingly, after ZFC the $M_s$ of both SLs were smaller than $M_s$ after FC, $\Delta M_s^{cSL}/M_s \approx -11\%$ for the cSL and $\Delta M_s^{mSL}/M_s \approx -3\%$ for the mSL.
Measurements of the ac electric transport were performed by means of four-probe method with silver paste contacts at the edges of the SLs. The ac-current amplitude was $I_{ac}=10 \mu A$ and the frequency $f_{ac}=17$ Hz. Besides the linear electric response with resistance $R_\omega$ at the fundamental frequency $f_{ac}$, we report the third harmonic response at $f_{3\omega}=3f_{ac}$ in terms of the coefficient $K_{3\omega}=\frac{U_{3\omega}}{U_\omega}$, which is a measure of the electrical nonlinearity in the film.\textsuperscript{21} Figure 5(a) shows the temperature dependence of $R_\omega$, measured after FC and ZFC. The cSL shows a large difference (factor of 10) between FC and ZFC resistance at low temperature, $T=10$ K. The difference gets smaller at $T=150$ K and vanishes completely close to $T_c=245$ K. The MI transition of the cSL is shifted by $\Delta T=77$ K below the magnetic transition. For the mSL no difference between $R_{\omega}^{\text{mSL}}$(FC) and $R_{\omega}^{\text{mSL}}$(ZFC) was observed, and $T_{c}\text{mSL}-T_{c}\text{mSL}=22$ K. Regarding nonlinear transport, shown in Fig. 5(b), the cSL shows a strong increase in $K_{3\omega}$ by decreasing temperature, both for FC and ZFC condition. Two features in $K_{3\omega}(T)$ are distinguishable: at $T=100$ K and $T=255$ K there exist kinks. Below $T=100$ K the nonlinearity is very large, $K_{3\omega}=\text{20 dB}$.

and nearly constant. For the mSL a very small nonlinear signal ($K_{3\omega} \approx 80 \text{ dB}$) was measured in the whole temperature range, both for FC and ZFC condition.

In the case of manganite-titanate interfaces, the concept of interface doping leads to an overall increase in the Mn valence, which would be equal to an increase in doping to $x = x_{\text{nominal}} + x_{\text{interface}}$. Recent theoretical and experimental studies show that the length scale on which charge transfer takes place is rather small, $L = 1 \text{ nm}$, and therefore $x$ is increased only in the vicinity of the interfaces. By adding LMO layers we decrease $x_{\text{nominal}}$ in this region. The overall doping level at the interfaces of the mSL is smaller compared to that at the cSL interfaces. In this sense, the interface regions bring about different electronic constraints to the LCMO layers in the SLs. Because of the strong electronic correlations these electronic constraints have tremendous impact on the structural properties of the LCMO layers.

First of all the enhanced saturation magnetization $M_s$ and reduced coercivity $H_c$ in mSL, see Fig. 4(a), directly show that the interface modification strongly reduces the tendency toward AFM correlation. The difference in $M_s$ after FC/ZFC and the extreme difference between $T_c$ and $T_M$ for the cSL underlines a pronounced magnetic inhomogeneity of the cSL. Due to the modification magnetic inhomogeneity is reduced in the mSL, which can also be seen in a somewhat steeper magnetic transition [see Fig. 4(b)]. The difference of the magnetic homogeneity is also reflected by the electric transport behavior of the SLs. The FC/ZFC difference, observed only for the cSL [see Fig. 5(a)], can be attributed to an inhomogeneous electronic (phase separated) state, which is known from La$_{1-x}$Ca$_x$MnO$_3$ with $0.4 \leq x \leq 0.5$.

Most interestingly, the different electric constraints of the SLs not only change the magnetic and transport properties but also the structure of the interface region and hence of the whole LCMO layers. For LCMO without oxygen deficiency, it was shown that crystalline structure, determined by the amount of Mn$^{4+}$ ions, changes from $R\overline{3}c$ for $x \approx 0.4$ to $Pnma$ for $x \approx 0.5$. The right oxygenation can be expected in the case of metal-organic aerosol deposition technique, as films are grown at ambient oxygen pressure. The manganite of the mSL shows $R\overline{3}c$ symmetry, which has been observed for small amounts of Mn$^{4+}$ ions, i.e., $x \approx 0.4$. The LCMO layers of the cSL show $Pnma$ symmetry, which is found for $x \approx 0.5$. So, most probably the interface region of cSL is in the CE-AFM state, as it is found for LCMO with $x \approx 0.5$. As we have shown previously, the manganites with $R\overline{3}c$ structure (LSMO) show linear transport behavior, whereas for the $Pnma$ structure nonlinearity has been observed in the transition region. Here we see another example of this rule: the mSL ($R\overline{3}c$) shows a very small $K_{3\omega} \approx 80 \text{ dB}$, whereas the cSL ($Pnma$) shows pronounced nonlinear transport properties, see Fig. 5(b). The extremely large nonlinear signal, $K_{3\omega} > 20 \text{ dB}$, at low temperatures on the other hand is in contrast to the results for single LCMO films. This can be attributed to the high density of interfaces of the cSL compared to a single LCMO film. The interfaces act like nucleation centers, at which the CP can accumulate and therefore the amount of CP is enhanced in cSL. If one assumes the CP to be the building blocks of the CE phase, it is clear that the interface region is unstable against the antiferromagnetic CE correlations.

For the mSL the number of CP is reduced so that $K_{3\omega}$ is very small. Furthermore the $Pnma$ symmetry, in contrast to the homogeneous $R\overline{3}c$ symmetry, allows for local elastic deformation. Phase separation into FM and CE-AFM, like it has been discussed for LCMO with $0.4 \leq x \leq 0.5$, can lead to the inhomogeneous magnetic and electric state of the cSL.

In summary we have shown that engineering of the doping profile in LCMO-BTO superlattices has massive influences on the magnetotransport properties. Only two monolayers of LMO at each interface lead to an enhancement of the saturation magnetization. Remarkable fact is that due to the interface modification also the crystal structure of the manganite layers changes. We discussed, that in conventional LCMO/BTO superlattices the ground state of the interfacial LCMO layers is likely CE-AFM, supporting theoretical calculations. This phase is responsible for exceptional nonlinear ($3\omega$) transport as well as for ZFC-FC splitting of the linear resistance discussed within correlated polaron model and phase-separation scenario.
